

Photodiode photovoltaic

Overview

A major non-ideality that affects photodiode systems is called dark current, because it is current that flows through the photodiode even when no illumination is present. The total current flow is.

The following diagram is an example of a photovoltaic implementation. This op-amp circuit is called a transimpedance amplifier (TIA). It is designed specifically to convert a current signal into a voltage signal.

To switch the above detector circuit over to photoconductive mode, we connect the photodiode's anode to a negative voltage supply instead of ground. The cathode is still at 0 V, but the current flows in the opposite direction.

The performance of a photodiode-based detector system is influenced by the photodiode's biasing conditions. Photoconductive mode employs reverse biasing and provides higher sensitivity, wider bandwidth, and improved linearity. Photovoltaic mode.

The basic output of a photodiode is current that flows through the device from cathode to anode and is approximately linearly proportional to illuminance. (Keep in mind, though, that the magnitude of the photocurrent is also influenced by the wavelength of the incident light—more on this in the next article.)
